<sup>1</sup>Weibull function b and c from Eqn 1 (stems); # refers to curve number in Fig. S1; 'r' denotes root curve available for *P. edulis*.

<sup>2</sup>van Genuchten  $\alpha$  and n for Eqn 2.

<sup>3</sup>Soil-canopy hydraulic conductance, k (mean[sd]), estimated from  $E/\Delta P$ , where  $\Delta P$  is difference between predawn and midday  $P_{\text{canopy}}$ . Values were excluded when E or  $\Delta P = 0$ , or when  $\Delta P$  was negative.

<sup>4</sup>Canopy diffusive conductance, G (mean[sd]).

<sup>5</sup>Vapor pressure deficit, D (mean[sd]).

<sup>6</sup>Predawn  $P_{\text{canopy}}$  (mean[sd]).

<sup>7</sup>Midday  $P_{\text{canopy}}$  (mean[sd]).

**Fig. S1** Weibull function vulnerability curves for the study species. Numbering as in Table S1

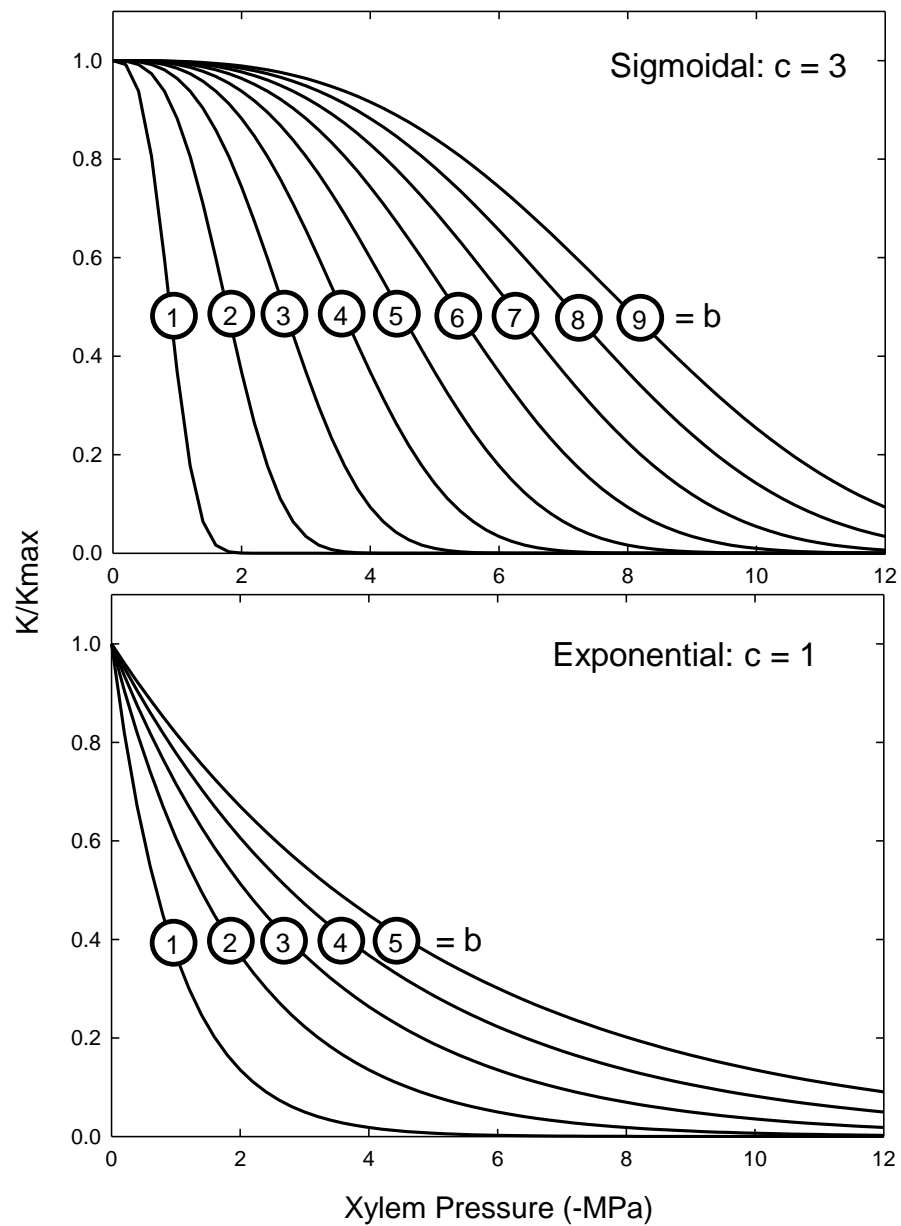

### Methods S1 Model fitting

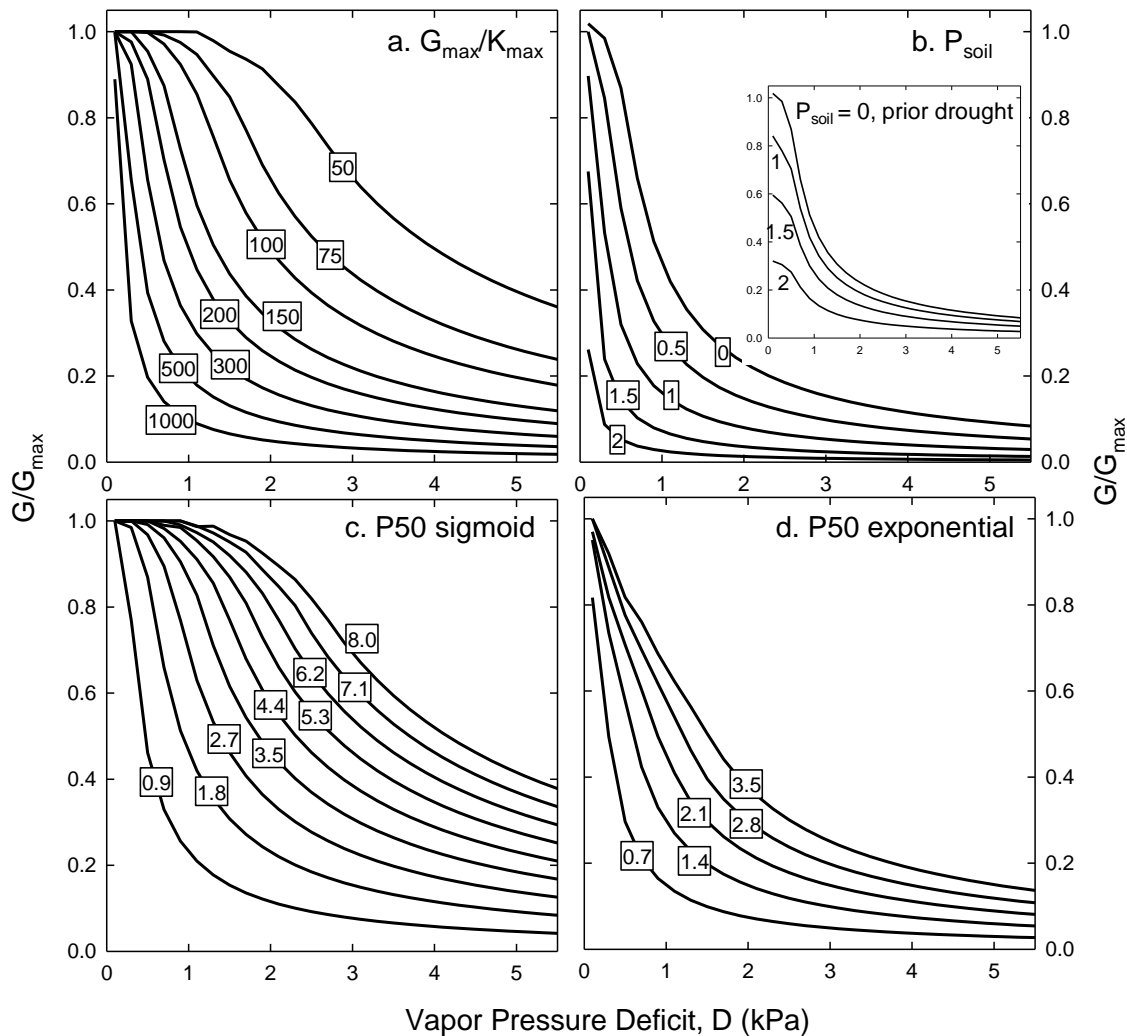

**Prior drought.** The importance of prior drought was estimated from experiments on the model. The model was driven by a data set to generate  $G$  and  $P_{\text{canopy}}$  outputs, using the extreme  $P_{\text{soil}}$  of the data set as the prior drought input. The downhill simplex routine was then used to fit the model *without* prior drought to these pre-droughted  $G$  and  $P_{\text{canopy}}$  outputs (via adjustment of  $G_{\text{max}}$ ,  $k_{\text{max}}$ , and % rhizosphere inputs). The mean absolute error between pre-droughted vs non-pre-droughted fits averaged less than 2.7% (error as percentage of mean pre-droughted  $G$  or  $P_{\text{canopy}}$ ). Data sets tested were numbers 1 (*Cavanillesia*, stem  $P_{50} = 1.11$  MPa), 5 (*Cojoba* dry,  $P_{50} = 2.80$  MPa), & 9 (*Cojoba* transitional dry,  $P_{50} = 4.63$  MPa; Fig. S1, Table S1); these were chosen to represent a wide range in cavitation resistance.

**Downhill simplex algorithm.** This algorithm requires an initial ‘simplex’ defined by four sets of  $G_{\text{max}}$ ,  $k_{\text{max}}$ , and % rhizosphere settings. Its performance was confirmed by fitting model output from the ‘wrong’ model input, converging to the correct values within 0.2%. To confirm a true global minimum was achieved when fitting data sets, the simplex was started from different settings. Only in a few cases (<10%) was this actually necessary.

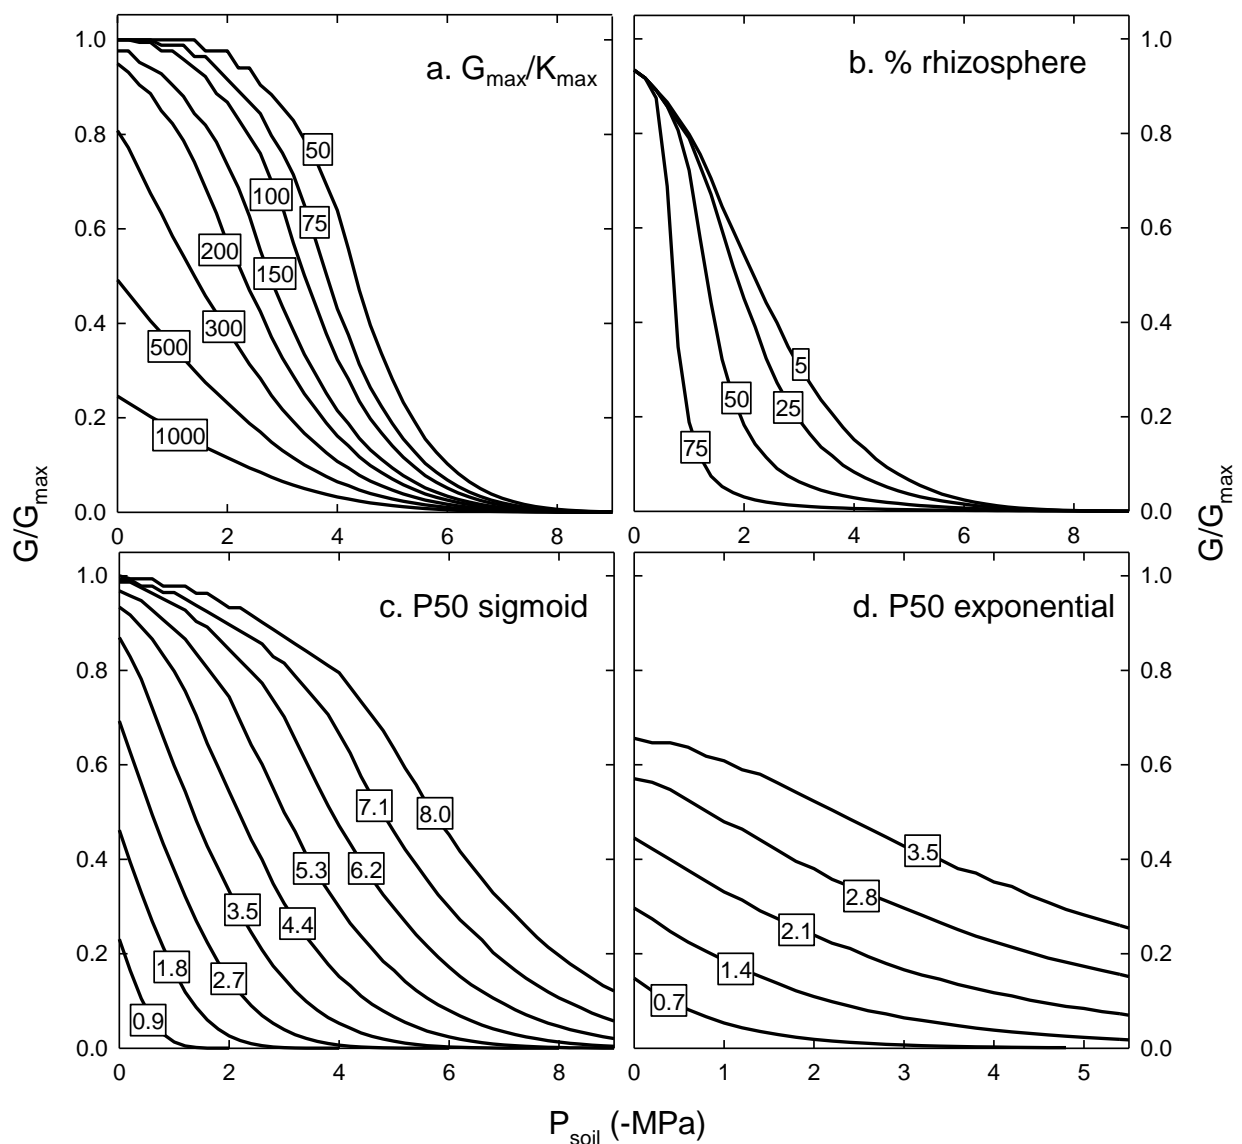

**Fig. S2** Sigmoid (Weibull  $c=3$ ,  $b$  varied as shown) and exponential ( $c=1$ ,  $b$  varied as shown) vulnerability curves tested in the sensitivity analysis of Figs S3 and S4.

**Fig. S3** Sensitivity of  $G$  to  $D$ . In each panel, all inputs were held at default settings (Table 1) except the input indicated. (a) Increasing the ratio of  $G_{\max}$  to  $k_{\max}$  (as labeled on curves) increased the closure response to  $D$ . (b) Drier soil (greater absolute  $P_{\text{soil}}$  as labeled) also increased the closure response to  $D$ . Inset shows the effect of exposure to *prior* drought (to the indicated  $P_{\text{soil}}$ ) on depressing  $G$  when  $P_{\text{soil}}$  has returned to 0 (all Inset curves are at  $P_{\text{soil}} = 0$ ). This resulted from irreversible cavitation during the drought; there was no prior drought effect when cavitation was reversible. (c) More vulnerable sigmoid vulnerability curves ( $P50$  as labeled; Fig. S2) increased the closure response to  $D$ . (d) More vulnerable exponential curves ( $P50$  as labeled; Fig. S2) also increased the closure response. Exponential curves produced immediate closure at lowest  $D$ , lacking the threshold response caused by sigmoid curves.

**Fig. S4** Sensitivity of  $G$  to  $P_{\text{soil}}$ . In each panel, all inputs were held at default settings (Table 1) except the input indicated. (a) Increasing the ratio of  $G_{\text{max}}$  to  $k_{\text{max}}$  (as labeled on curves) increased the rate of stomatal closure, but without changing the  $P_{\text{soil}}$  at complete closure. (b) Greater % rhizosphere resistance increased closure from  $P_{\text{soil}}$ , while also restricting  $P_{\text{soil}}$  at complete closure. (c) More vulnerable sigmoid vulnerability curves (P50 as labeled) increased the closure response and restricted  $P_{\text{soil}}$  at complete closure. (d) More vulnerable exponential curves (P50 as labeled) increased closure, but the closure occurred at a slower rate than for the sigmoidal case, owing to the long tail on the exponential curve (Fig. S2).

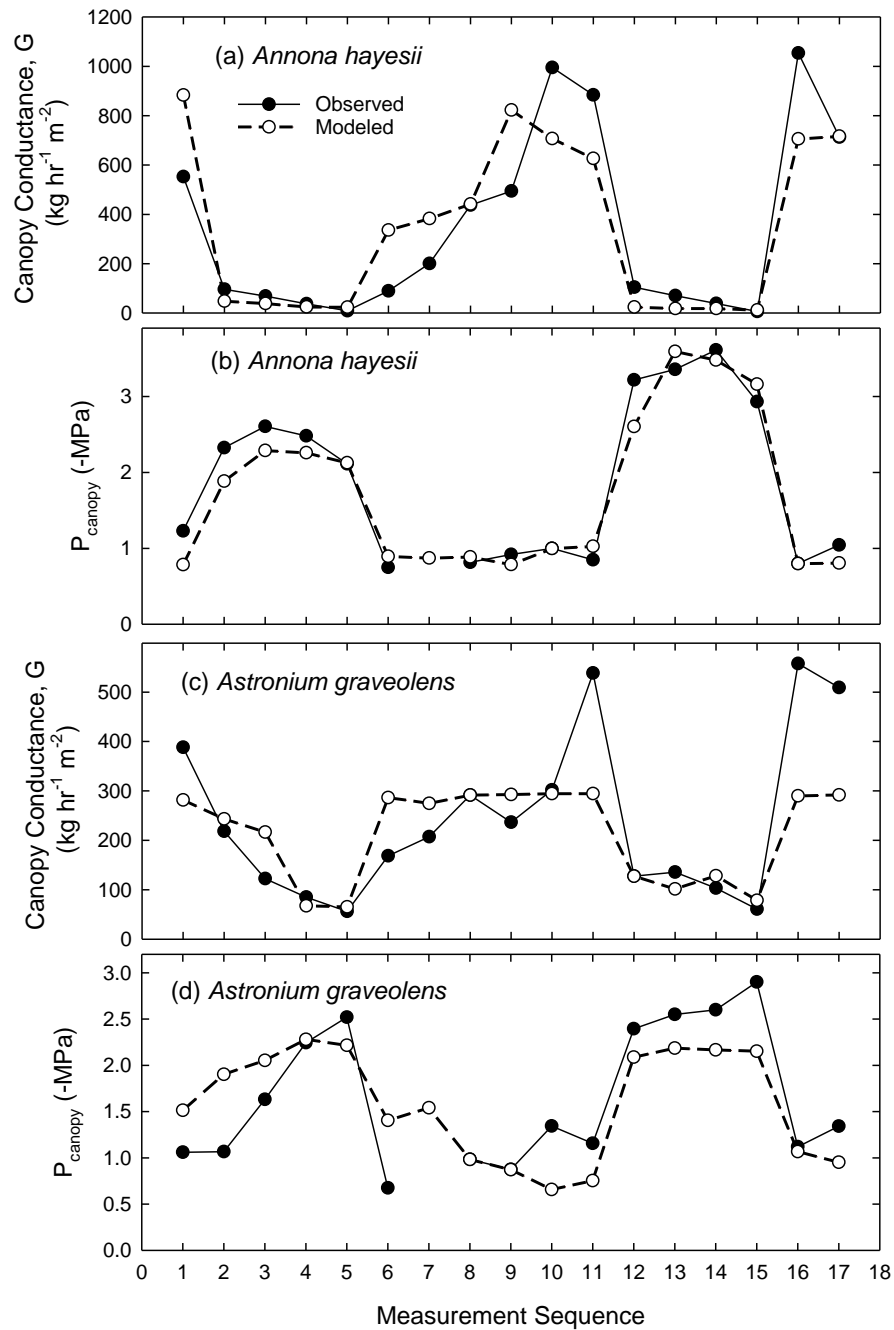

**Fig. S5** Fig. 6 in the text, but with unlimited  $G_{\max}$ . Maximum intercepts increased because they were no longer limited by  $G_{\max}$ . Slopes became solely a function of the Weibull 'c' parameter.

**Fig. S6** The effect of the % rhizosphere setting (5, 25, 50% heavy curves) on the midday vs predawn  $P_{\text{canopy}}$  relationship. A single Weibull  $b=2$  setting is shown, for  $c = 0.7$  to 20 (dashed lines). The default 5% rhizosphere setting had a minimum slope of ca. 0.2 (as in Fig. S5). Increasing the % rhizosphere resistance dropped the minimum slope to zero and below. The intercept was minimally altered.

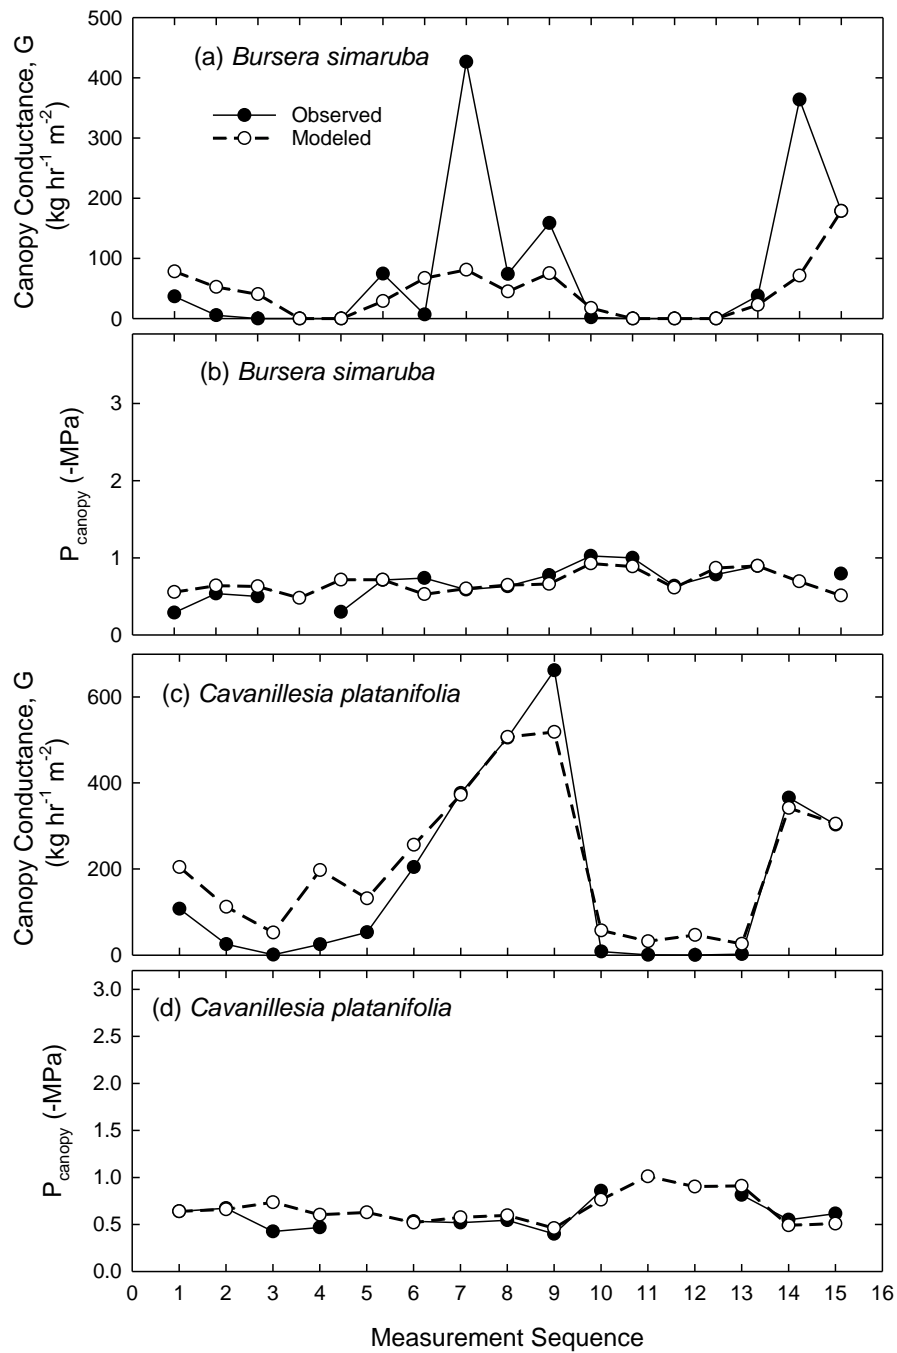

**Fig. S7** Sequence of observed (closed symbols) and modeled (open symbols) canopy conductance ( $G$ ) and  $P_{\text{canopy}}$ . Model set to irreversible cavitation. Measurements were made every 3–6 wk from November 2011 to July 2013, through two wet and two dry seasons in Panama. (a) *Annona hayesii*  $G$ . (b) *A. hayesii*  $P_{\text{canopy}}$ . (c) *Astronium graveolens*  $G$ . (d) *A. graveolens*  $P_{\text{canopy}}$ .

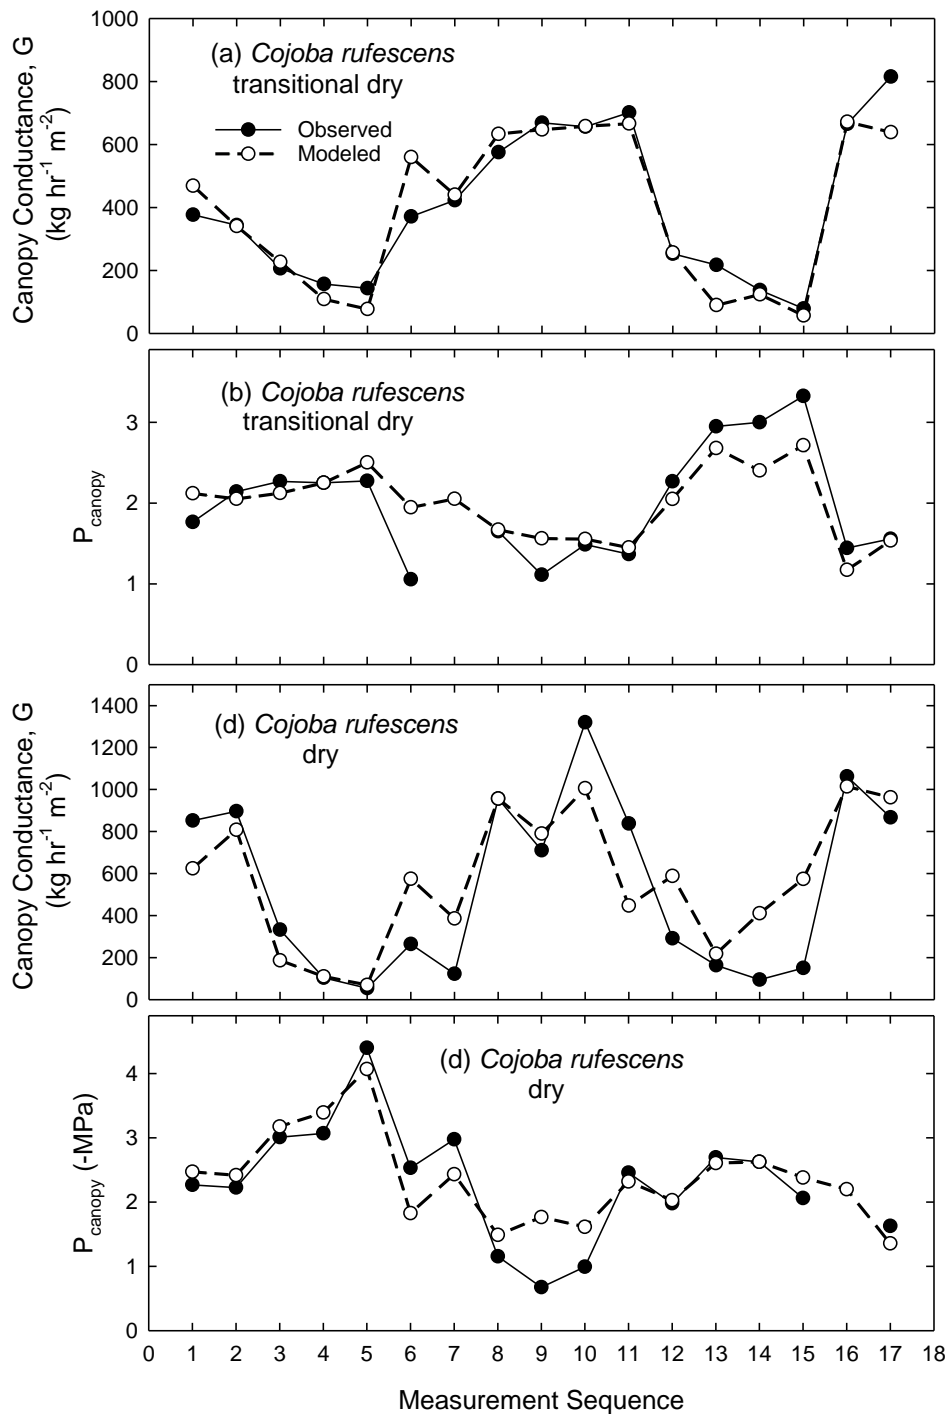

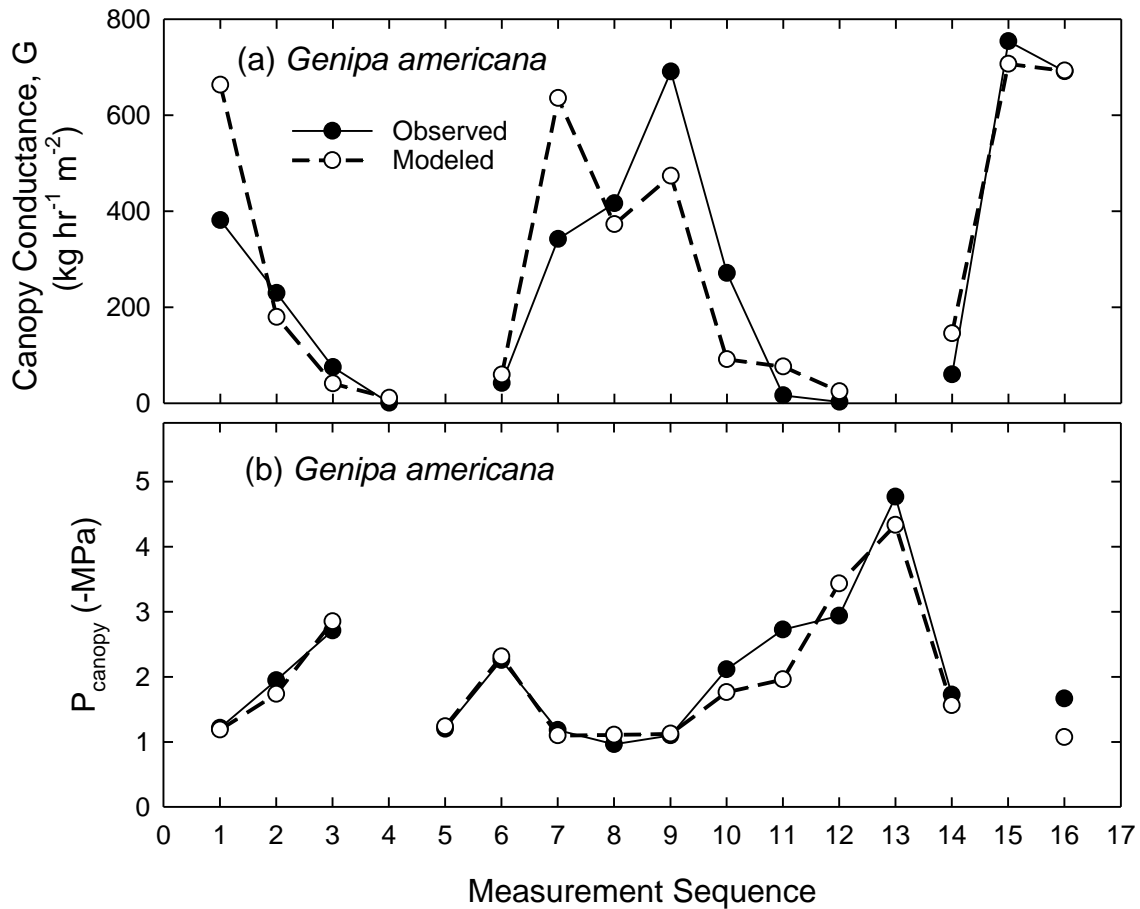

**Fig. S8** Sequence of observed (closed symbols) and modeled (open symbols) canopy conductance ( $G$ ) and  $P_{\text{canopy}}$ . Model set to irreversible cavitation. Measurements were made every 3–6 wk from November 2011 to July 2013, through two wet and two dry seasons in Panama. (a) *Bursera simaruba*  $G$ . (b) *B. simaruba*  $P_{\text{canopy}}$ . (c) *Cavanillesia platanifolia*  $G$ . (d) *C. platanifolia*  $P_{\text{canopy}}$ .

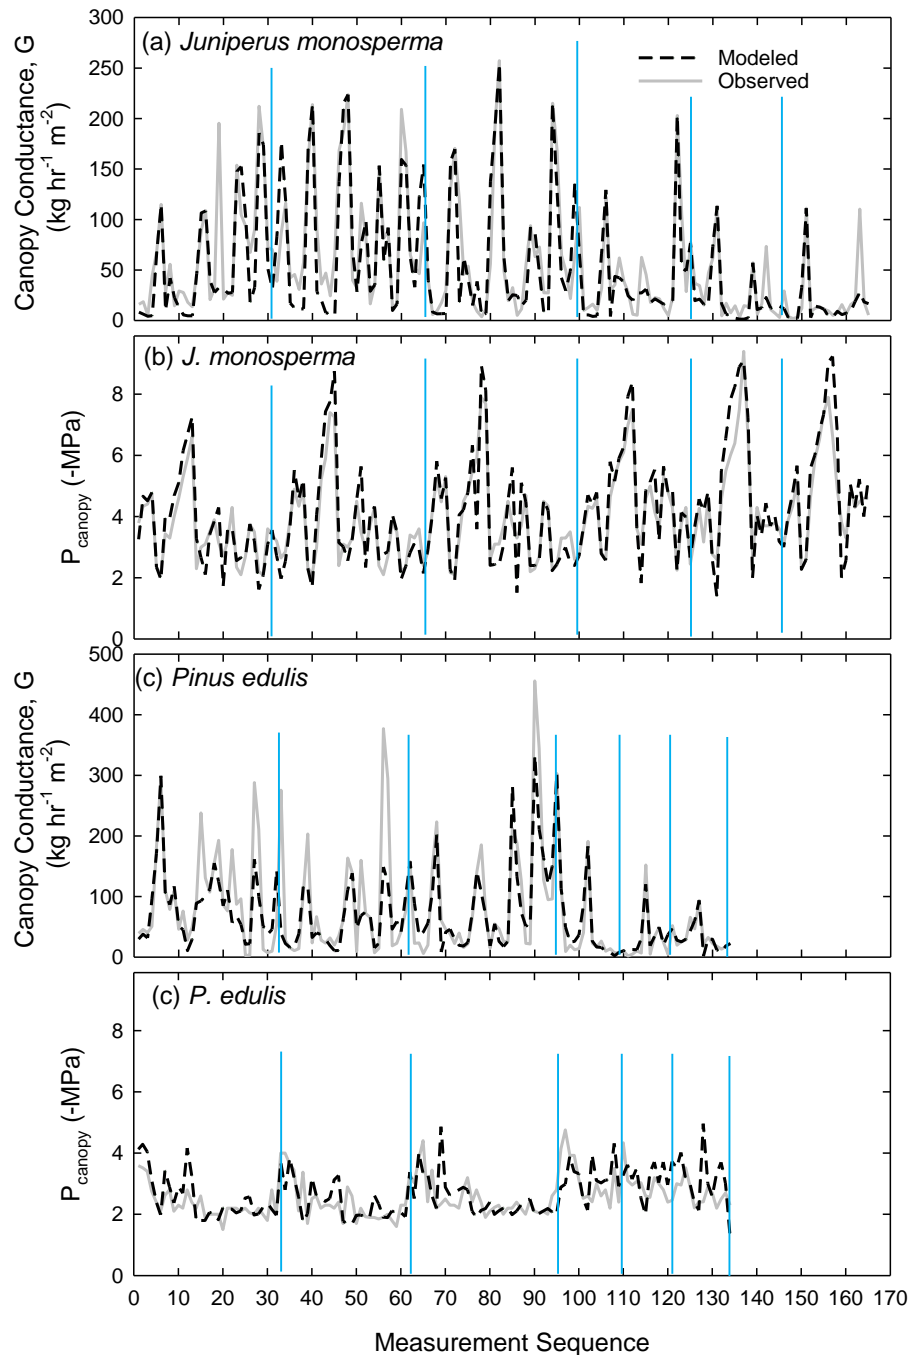

**Fig. S9** Sequence of observed (closed symbols) and modeled (open symbols) canopy conductance ( $G$ ) and  $P_{\text{canopy}}$ . Model set to irreversible cavitation. Measurements were made every 3–6 wk from November 2011 to July 2013, through two wet and two dry seasons in Panama. (a) *Cojoba rufescens* (dry forest)  $G$ . (b) *C. rufescens* (dry forest)  $P_{\text{canopy}}$ . (c) *C. rufescens* (transitional dry forest)  $G$ . (d) *C. rufescens* (transitional dry forest)  $P_{\text{canopy}}$ .

**Fig. S10** Sequence of observed (closed symbols) and modeled (open symbols) canopy conductance ( $G$ ) and  $P_{\text{canopy}}$ . Model set to irreversible cavitation. Measurements were made every 3–6 wk from November 2011 to July 2013, through two wet and two dry seasons in Panama. (a) *Genipa americana*  $G$ . (b) *G. americana*  $P_{\text{canopy}}$ .

**Fig. S11** Sequence of observed (dashed black) and modeled (grey) canopy conductance ( $G$ ) and  $P_{\text{canopy}}$  for *Juniperus monosperma* and *Pinus edulis*. Model set to irreversible cavitation. An average of 8 measurement days were spaced over the 7 month (April–October) growing season for 2007–2010. The model was run on 6 trees per species, each tree shown sequentially and demarked by vertical blue lines. Each growing season per tree was fit separately. The final three *P. edulis* trees and last *J. monosperma* tree died after two growing seasons.

**Table S2** Model fit statistics, fitting parameters, average observed G and plant hydraulic conductance ( $G_{ave}$ ,  $k_{ave}$ ), and stem P50's for 9 data sets as plotted in Fig. 9. Model was run in reversible cavitation mode.

<sup>1</sup>Mean absolute error, and its percentage of the observed mean; P<sub>canopy</sub> in –MPa, G in kg h<sup>-1</sup> m<sup>-2</sup>.

<sup>2</sup>‘Dry’ and ‘transitional’ refer to the forest type; B. Wolfe *et al.* (unpublished).

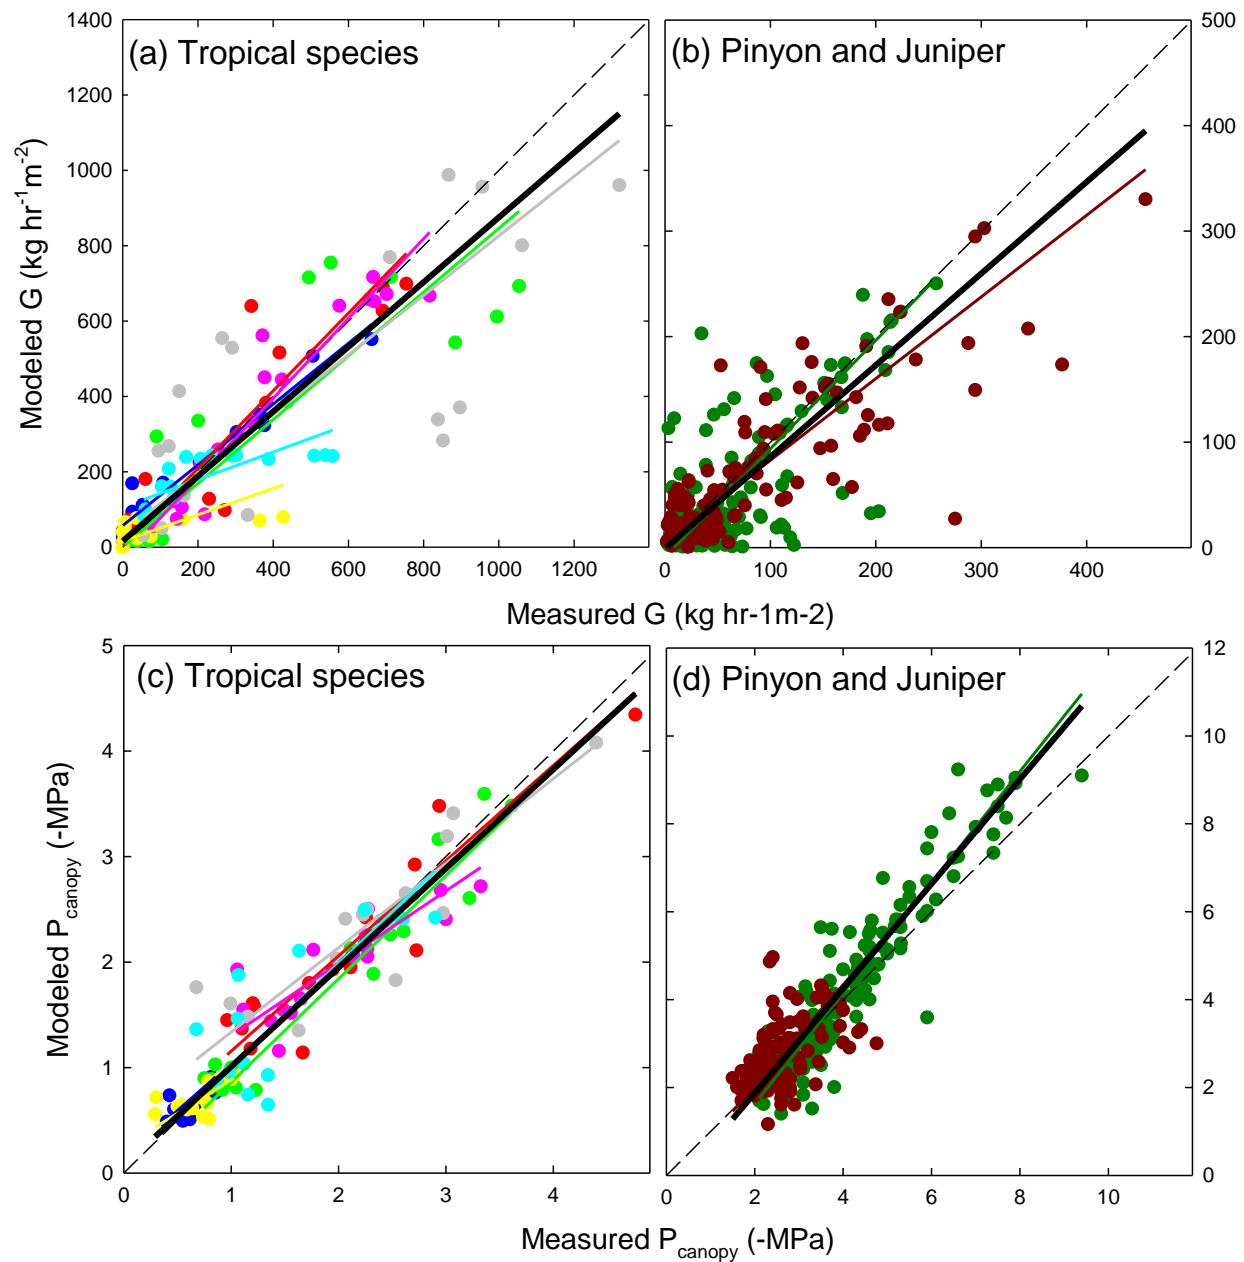

<sup>3</sup>McDowell *et al.* (2013).

<sup>4</sup>G<sub>ave</sub> and k<sub>ave</sub> are observed averages in the data sets.

<sup>5</sup>SD+ is number of standard deviations that G<sub>max</sub> or k<sub>max</sub> is above their measured means.

<sup>6</sup>P50 is in –MPa.

**Fig. S12** Modeled vs measured  $G$  (a, b) and  $P_{\text{canopy}}$  (c, d) for the seven tropical (a, c) and two piñon-juniper (b, d) data sets. Reduced major axis regressions shown for each data set (colored lines) and the entire panel (black line), along with dashed 1:1 line. Light green, *Annona*; cyan, *Astronium*; yellow, *Bursera*; blue, *Cavanillesia*; pink, *Cojoba* transitional dry; grey, *Cojoba* dry; red, *Genipa*; dark green, *Juniperus*; dark red, *Pinus*. Model was set to reversible cavitation.

## Notes S1 Model experiments on % rhizosphere compensation

The ability of % rhizosphere setting to compensate for missing xylem segmentation was tested in data sets 1 (*Cavanillesia*, stem P50 = 1.11 MPa), 5 (*Cojoba* dry, P50 = 2.80 MPa), & 9 (*Cojoba* transitional dry, P50 = 4.63 MPa; Fig. S1, Table S1). These sets were chosen to represent a wide range in cavitation resistance. For each data set, the model was segmented, assuming the leaf and root xylem P50 was 50% of the stem value (via adjustment of the Weibull b parameter only). The rhizosphere was set to the default of 5%, and  $G_{\max}$  and  $k_{\max}$  were set to best fit values (from Table 1). The model was driven by the data set sequence of D and predawn pressure to generate ‘true’ segmented G and  $P_{\text{canopy}}$  outputs. The segmentation was then removed (all xylem was given the stem vulnerability curve), and the downhill simplex routine was used to fit the segmented G and  $P_{\text{canopy}}$  outputs (via adjustment of  $G_{\max}$ ,  $k_{\max}$ , and % rhizosphere inputs). The fitting reduced the average absolute error in  $P_{\text{canopy}}$  from 19.6% to 4.9% (% of mean segmented value), and average G error from 144.1% to 25.3%. The best-fit % rhizosphere rose an average of 1417% from 5% to 76%. Best fit  $G_{\max}$  and  $k_{\max}$  fell an average of 2.3% and 22.1%. The largest best-fit error was for G (45%) in the most vulnerable species (1, *Cavanillesia*), reflecting the fact that the % rhizosphere setting has the most effect in dry soils, by which point *Cavanillesia* was already shut down by cavitation.
